Hypoxia inducible factor Cancer stem cell

Keywords: Cancer Hypoxia

ABSTRACT

Cancer stem cells (CSC) constitute a small area of the tumor mass and are characterized by self-renewal, differentiation and the ability to promote the development of secondary chemo-resistant tumors. Self-renewal of CSCs is regulated through various signaling pathways including Hedgehog, Notch, and Wnt/β-catenin pathways. A few surface markers have been identified, which provide a means of targeting CSCs according to tumor type. Depending on the proximity of CSCs to the tumor hypoxic niche, hypoxia-inducible factors (HIFs) can play a critical role in modulating several CSC-related characteristics. For instance, the upregulation of HIF-1 and HIF-2 at tumor sites, which correlates with the expansion of CSCs and poor cancer prognosis, has been demonstrated. In this review, we will discuss the mechanisms by which hypoxia enhances the development of CSCs in the tumor microenvironment. Targeting HIFs in combination with other common therapeutics is pre-requisite for effective eradication of CSCs.

1. Introduction

The tumor microenvironment consists of cancer, perivascular, endothelial and other cells that provide immunosuppressive signals that compromise the activity of tumor-infiltrating leukocytes by various mechanisms [\[1\]](#page-10-0). Cancer cells use various mechanisms to evade antitumor immune responses. It has been shown that the lack of efficient oxygenation within the tumor center induces hypoxia and hypoxia-related factors, which correlate with tumor progression [\[2\]](#page-10-1). Although hypoxia is one of the important escape mechanisms within the tumor microenvironment, it should be noted that hypoxia generation is a function of tumor growth and it is a physiological effect of fast growth and not enough circulation. Hypoxia extensively shapes the tumor microenvironment by modulating the transcription of hundreds of genes, which regulate tumorigenesis, angiogenesis, invasion, metastasis, drug-resistance, and immune suppression. Hypoxia-inducible factor-1 (HIF-1) is an important transcription factor induced in tumor cells following oxygen deficiency, which plays a critical role in several tumor-promoting processes regulating cancer cell survival and cancer progression. HIF-1 consists of two subunits, HIF-1 α and HIF-1 β ; HIF-1 β is constitutively expressed, whereas expression of HIF-1 α is oxygendependent and induced in response to acute hypoxic conditions. There are two HIF α subunits, HIF-1 α and HIF-2 α . Although they are homologous and bind to similar hypoxic response elements (HREs), there are some structural differences between isoforms. For example, the Nterminal transactivation domain (N-TAD) is variable between HIF-1α and HIF-2 α and increases the expression of target genes which are specific in each subunit, however, (C-TAD) contributes to target genes that are common between HIF-1α and HIF-2α [[3](#page-10-2)]. On the other hand, HIF-1 α preferentially increases the expression of genes that are involved in the glycolytic pathway, and HIF-2 α is contributed to the regulation of genes crucial for cell cycle progression, tumor growth, and maintaining stem cell pluripotency, like stem cell factor OCT-3/4 and the proto-oncogene c-Myc [[4](#page-10-3)[,5\]](#page-10-4). HIF factors are involved in several

tumor-promoting processes such as survival, proliferation, angiogenesis, invasion, metastasis and tumor recurrence via differentiation of cancer stem cells (CSCs) [\[6,](#page-10-5)[7](#page-10-6)]. CSCs (also known as tumor-initiating cells) are present in various cancers and can enhance tumor onset, progression, and metastasis [\[8\]](#page-10-7). Expression of various embryonic factors such as Sox2, Nanog, and Oct4 by CSCs enhances properties such as embryogenesis, pluripotency, and self-renewal [[9](#page-10-8)]. There is evidence that indicates the role of HIF-1α and HIF-2α in CSC-induced cancergrowth and recurrence. Accordingly, it has been demonstrated that direct binding of HIF-2 α to the HRE located in the promoter regions enhances expression of Sox2, Nanog and Oct4 [\[10](#page-10-9)]. CSCs can be discriminated from other cells by expression of some surface molecules such as CD133, CD24, and CD44. Consequently, HIFs control CD133 promoter activity and increase the proliferation of CD133-expressing CSCs [\[11](#page-10-10)]. Although the precise molecular mechanisms that drive the development of CSCs by HIFs are not completely understood, targeting hypoxia-related factors is a potential strategy for inhibiting CSC-associated cancer recurrence and chemo-resistance. In this review, we will discuss the role of hypoxia and HIFs in the growth and development of CSCs and their potential as therapeutic targets for the eradication of CSCs and suppression of cancer recurrence. (see [Table 1](#page-2-0))

2. HIF and cancer progression

Tumorigenesis is a complex and multi-step process, which is related in part to the interplay between several tumor-driving metabolic pathways, factors, and cells and the development of the tumor microenvironment. The rapid proliferation of cancer cells in combination with inefficient blood supply leads to oxygen deficiency in the tumor center. To compensate oxygen deficiency and adaptation within the tumor microenvironment, cancer cells use various metabolic pathways such as activation of HIF factors, which are the most prominent reg-ulators of oxygen homeostasis [[12,](#page-10-11)[13\]](#page-10-12). HIF factors consist of HIF- α and HIF-β subunits in which expression of the α -subunit is oxygen-dependent, whereas β-subunit is constitutively expressed [\[14](#page-10-13)[,15](#page-10-14)]. In response to decreased oxygen levels, cancer cells in solid tumors express the HIF-1 transcription factor that induces expression of several factors involved in cancer progression: processes including extracellular matrix remodeling, angiogenesis, cell migration, metastasis, epithelial-mesenchymal transition (EMT), drug resistance, and maintenance of CSCs [[16\]](#page-10-15).

Angiogenesis is a prerequisite for tumor development and is robustly promoted by the upregulation of vascular endothelial growth factor (VEGF) at the tumor site. The expression of VEGF is strictly induced by HIF-1 upon the onset of hypoxia in the tumor microenvironment. This relationship has been confirmed by using a HIF-1αdeficient experimental model, which is associated with significant downregulation of VEGF expression. Moreover, HIF orchestrates the migration of endothelial cells to hypoxic areas to facilitate the generation of blood vessels to overcome oxygen deficiency [[17,](#page-10-16)[18\]](#page-10-17).

In hypoxic tumors, anaerobic metabolism pathways are more prominent compared to oxidative phosphorylation to maintain ATP generation [\[19](#page-10-18)]. On the other hand, glucose metabolism is regulated in the hypoxic tumor microenvironment by HIF-1 as tumor cells express several HIF-1-regulated genes involved in glucose metabolism to adapt to oxygen deficiency [[20\]](#page-10-19). Concomitantly, HIF-1 upregulates GLUT1 and GLUT3 glucose transporters, facilitates the conversion of glucose to pyruvate, and induces enzymes responsible for clearance of pyruvate [[21](#page-10-20)[,22](#page-10-21)]. In addition to the regulation of metabolic pathways, HIF can also modulate tumor-infiltrating immune cells. It has been shown that HIF-1 α recruits and increases the function of suppressive cells including tumor-associated macrophages and myeloid-derived suppressor cells (MDSCs) in the hypoxic tumor microenvironment [[23](#page-10-22)[,24](#page-10-23)]. This recruitment is in part through upregulation of chemokines such as CCL5, CXCL12, and the cytokine VEGF, which attracts myeloid cells [[25,](#page-10-24)[26](#page-10-25)]. Induction of hypoxia-related signaling in MDSCs and tumor-associated

macrophages by HIF leads to their recruitment into the tumor site and increases their suppressive function [\[27](#page-10-26)]. Following recruitment, tumor-associated macrophages secrete MMP-9, which upregulates VEGF in the tumor region and promotes tumor angiogenesis, metastasis and subsequently progression [\[25](#page-10-24)]. The suppressive effect of hypoxic tumor region on immune cells, particularly by HIF-1α, is associated with the upregulation of adenosine levels in tumor sites and adenosine receptors on tumor-infiltrating immune cells. Signaling of A2AR on T cells inhibits their proliferation and cytokine production [[28,](#page-10-27)[29\]](#page-10-28). HIF- 1α also induces the expression of immunosuppressive molecules including programmed death-ligand 1 (PD-L1) on cancer cells and CTLA-4 on $CD8⁺$ T cells, which reduce T cell-mediated anti-tumor responses [[30\]](#page-11-0). Tregs are other hypoxia targets present in the tumor microenvironment. HIF-1 α induces FoxP3 expression in T cells, thereby increasing the frequency and function of Tregs in the tumor microenvironment. Cancer cells secrete Treg-specific chemo-attractants such as TGF-β and CCL28, which recruit CCR10-, neuropilin-1- and CXCR10 expressing Tregs into the tumor microenvironment.

Intriguingly, cancer cells not only induce HIF signaling following hypoxic stress, but also they use various oxygen-independent pathways for promoting HIF expression, stability, and downstream signaling pathways. For example, the constitutive expression of oncogenes or mutation of tumor suppressor genes can activate HIF-1α in an oxygenindependent manner in the tumor microenvironment [\[31](#page-11-1)]. One of the HIF-regulating tumor suppressors, von Hippel-Lindau protein (vHL), regulates HIF expression via proteasomal degradation and ubiquitination in normoxic conditions. The hydroxylation of proline 402 and 564 in the human HIF1 α is involved in its degradation. vHL in complex with elongin B and C recognizes hydroxylated prolines and then acts with neDD8 as an E3 ubiquitin ligase that alters HIF1α and targets it for degradation. Since Prolyl hydroxylases (PHDs) has low affinity to O2, HIF1 α is not hydroxylated under O2 tension condition and becomes stabilized [\[32](#page-11-2)]. vHL ubiquitin ligase complex cannot undergo HIF-1 ubiquitination under hypoxic conditions; instead, it is translocated to the nucleus, where it forms a complex with HIF-1β. This is followed by upregulation of target genes via binding to the HRE in the promoter. The binding of C-TAD and co-activators CBP/p300 is mandatory for the expression of HIF-1 α target genes. Loss of vHL expression in renal cancers leads to constitutive expression of HIF1 α and HIF2 α (even in normoxia) resulting in stimulation of target genes and loss of VHLmediated tumor suppression [\[33](#page-11-3)]. Under normoxic conditions, factor inhibiting HIF-1 (FIH-1) promotes hydroxylation of C-TAD and blocks transcription of HIF-1α. On the other hand, hypoxic conditions inhibit hydroxylation and enhance transactivation of HIF-1α [[34\]](#page-11-4). Therefore, the expression of HIF by CSCs under both hypoxic and normoxic conditions is considered advantageous, due to its ability to promote tumorigenesis and regulate the expression of over 100 tumor-associated genes.

3. Biological properties of cancer stem cells

CSCs constitute a small group of cells in tumors, which are mainly involved in cancer recurrence, metastasis, and chemo-resistance. CSCs exhibit various characteristics including self-renewal, asymmetric division, promotion of EMT and chemo-resistance. Based on cancer type, CSCs can be discriminated from other cells via expression of surface molecules including CD44, CD24, CD133, Lgr5, and CD166, which can be used to specifically target these cells [\[35](#page-11-5)]. Despite several hypotheses on the origin of CSCs, their precise origin remains elusive. However, it is assumed that they originate from normal tissue progenitor cells, differentiated somatic cells, or even from tumor cells. They were first detected in human acute myeloid leukemia (AML), and subsequently identified in several hematopoietic and solid tumors such as breast, colon, brain, lung, pancreas, liver, ovarian, melanoma, prostate, bladder, and head and neck [\[36](#page-11-6)].

Fig. 1. Molecular pathways activated in cancer stem cells under hypoxia in tumor microenvironment. In the tumor microenvironment blood vessels often do not function properly which results in poor O₂ supply to the center of tumor region. Following activation, HIF-1α and HIF-2α translocate to the nucleus and make a complex with HIF-β in cancer cells under hypoxic condition, which leads to expression of several downstream genes involved in CSCs development, self-renewal, expression of stemness factors, induction of angiogenic factors, and upregulation of stem cell markers including CD44 and CD133. Stimulation of PI3K/Akt/mTOR pathway enhances the stabilization of HIF-α. Induction of STAT3 in a jak-mediated manner or through stimulation of adenosine receptor 2B enhances the expression of interleukin 6 and Nanog, which is associated with cancer stem cell phenotype. Stabilization of notch intracellular domain (NICD) by HIF-1α and HIF-2α leads to the upregulation of Notch-responsive genes. HIFs: hypoxia-inducible factors, PI3K: Phosphatidylinositol 3-kinase, mTOR: mammalian target of rapamycin, VEGF: vascular endothelial growth factor, ALDH: Aldehyde dehydrogenase, ABCG2/BCRP: breast cancer resistance protein, MAPK: mitogen-activated protein kinase.

tumor bulk in immunodeficient animals [\[37](#page-11-32)]. Signals derived from tumor microenvironment can induce differentiation of CSCs into cancer cells. Interestingly, other signals from the tumor microenvironment promote the differentiation of cancer cells into CSCs [\[38](#page-11-33)]. There are various factors including niche cells and cytokines in the CSC niche, which induce CSC development. T helper (Th) cells and tumor-associated macrophages release TNFα and induce NF-κB signaling in CSCs present in the inflammatory CSC niche, leading to upregulation of factors such as Twist, Snail, and Slug, EMT and CSC self-renewal [[39](#page-11-34)[,40](#page-11-35)].

Nanog, Oct4, and Sox2 are three main transcription factors, which are critically involved in self-renewal and pluripotency of embryonic stem cells (ESCs) and CSC-like cells (CSCLCs). The upregulation of these factors has been demonstrated in various cancer types and associated with tumorigenesis, transformation, and metastasis [\[41](#page-11-36)]. Among these factors, Oct4 inhibits apoptosis and increases the proliferation of CSCLCs partly via the Oct4-TCL1-AkT1 pathway [\[9,](#page-10-8)[42\]](#page-11-37). On the other hand, Nanog upregulates CD44, CD133, ALDH1A1, and ABCG2 in CSCs, promoting survival and drug resistance in these cells [[43\]](#page-11-38). Besides, the upregulation of Sox2 enhances tumorigenesis and sphere formation by CSCs [[44\]](#page-11-39).

Notch, Wnt/β-catenin, and Hedgehog are the main signaling pathways involved in the regulation of CSC. Wnt/β-catenin, which is a pivotal signaling pathway for tumorigenesis, is the most critical pathway for regulating CSCs self-renewal. In the absence of ligand binding with the Wnt receptor, β-catenin generates the APC-degrading complex in the cytoplasm. On the other hand, stimulation of Wnt signaling stabilizes βcatenin and leads to its association with TCF/LEF and upregulation of target genes including CCND1/2, Sox4, c-MYC, TCF7, Axin2, LGR5, and ASCL2. Accordingly, blockade of the Wnt/β-catenin pathway leads to the downregulation of CSCs maintenance [[45\]](#page-11-40).

In addition to exerting critical effects on the regulation of embryogenesis, differentiation, proliferation, and apoptosis, Notch signaling is also required for self-renewal of CSCs. Following ligand binding, ɣsecretase and metalloprotease cleave Notch receptors and deliver the active Notch intracellular domain (NICD) to the cytosol. Translocation of NICD to the nucleus and its binding with the core binding factor-1 (CBF-1) leads to the expression of downstream genes such as HES family genes, HEY family genes, and NRARP [\[46](#page-11-41),[47\]](#page-11-42).

Constitutive signaling of the Hedgehog pathway can lead to tumorigenesis. While the Smo receptor induces the Hedgehog signaling pathway, the Patched receptor blocks it. Expression of Hedgehog target genes leads to the development of CSCs and tumor progression. Therefore, targeting these three pathways involved in the generation and development of CSCs should be therapeutic strategies for suppressing cancer recurrence.

4. Hypoxia and CSCs

Hypoxia and HIF factors can exploit various mechanisms to affect the induction and development of CSCs. These factors may promote the propagation of CSCs through induction of CSC markers, CD44 and ALDH, adenosine/STAT3/IL-6 pathway, MAPK/ERK pathway, NOTCH and WNT signaling, or other mechanisms.

4.1. Induction of cancer stem cell markers

CSCs in various cancers can be identified by the expression of various surface-expressed markers. Several studies indicate HIFs can induce the expression of CSC markers.

CSCs in glioblastoma (GBM), which are also known as GBM stem cells (GSCs), participate in tumor recurrence and progression. It has been demonstrated that hypoxic conditions can induce a GSC phenotype and enhance the expression of GSC associated markers. While both the GSCs and neural progenitor cells express HIF-1α, HIF-2α is only expressed by GSCs. Interestingly, HIF-2 α is expressed in GSCs in both

acute hypoxic and normoxic conditions, which shows it can act in an oxygen-independent manner. Therefore, HIF-2 α may be considered as a GSC-specific marker [[48\]](#page-11-43). Consequently, transfection of non-stem glioma cells (T4121) with HIF-2 α led to the induction of major stem cell markers, including Oct4, Nanog and c-MYC indicating that HIF-2α is a pivotal transcription factor for inducing a GSC phenotype [\[49](#page-11-7)]. CD133⁺ cells purified from human brain tumors have stem cell features, which implies that CD133 can be used as a GSC marker [\(Fig. 1](#page-5-0)). $CD133⁺$ cells can also induce tumor formation in the brains of NOD-SCID mice $[50]$ $[50]$. The frequency of CD133⁺ cells and concomitant upregulation of various stem cell markers such as Klf4, nestin, Sox2, and Oct4 can also be induced in hypoxic conditions. There is evidence that HIF-1 α can regulate de-differentiation of more than 95% of residual differentiated cells (CD133⁻CD15⁻NESTIN⁻) to tumorigenic GSC-like cells $(CD133 + CD15 + NESTIN⁺)$ and play an important role in maintaining of GSCs stemness feature [51–[53\]](#page-11-8). Besides, while hypoxia induces both the HIF1 and HIF2 in $CD133⁺$ cells, expression levels of HIF-2α are significantly higher than HIF-1α in these cells [\[54](#page-11-11)]. However, self-renewal of CD133-expressing GSCs is linked to the upregulation of HIF-1α under hypoxic conditions and silencing HIF-1α suppressed expansion of these cells [\[55](#page-11-12)]. Moreover, the culture of multidrug resistant CML K562/DOX cells under hypoxic conditions led to the expression of stem cell markers including CD133, CD34, and Oct4 by HIF-1α in a TGF- $β$ /Smad2/3 signaling-dependent manner [\[56](#page-11-13)]

Cancer stem-like cells, characterized by CD133 expression, have also been detected in patients with lung cancer. $CD133^+$ ESA⁺ cells exhibited high tumorigenic potential in primary non-small cell lung cancer (NSCLC) [\[57](#page-11-45)]. Exposure of PC9 and HCC827 NSCLC cells to high amounts of gefitinib under hypoxic conditions for seven days led to the survival of a small fraction of cells, termed gefitinib-resistant persisters (GRPs). These cells had the high sphere-forming ability and expressed high levels of stem cell factors such as CD133, Nanog, ALDH1A1, and Oct4. Moreover, hypoxia induced the expression of insulin-like growth factor 1 (IGF1) and activated IGF1 receptor (IGF1R) on the resistant cells in the HIF-dependent manner, which was associated with the development of CSCs resistant to gefitinib. Therefore, it is likely that inhibition of HIF-1 α and targeting the IGF1R pathway decreases the po-pulation of CD133⁺ and Oct4⁺ resistant CSCs in lung cancer [[58\]](#page-11-14). Lida and colleagues also detected the increased expression of CD133 in the lung cancer cell lines A549, H358 and N417, following the culture of these cells under low oxygen conditions. They showed that the activity of the P1 promoter of the CD133 gene locus is robustly linked to hypoxia-induced promoter activity. They also demonstrated the direct binding of Oct4 and Sox2 to the P1 region using the chromatin immunoprecipitation assay. Interestingly, hypoxia-mediated expression of CD133 was related to HIF-1α- and HIF-2α-induced expression of Sox2 and Oct4. Consequently, silencing Sox2 or Oct4 in N417 cells suppressed HIF-induced CD133-P1 activity. Therefore, it seems that hypoxia (HIF-1α/HIF-2α) promotes the development of CD133-expressing CSCs through Sox2 and Oct4 in lung cancer cells by binding to the P1 region of the CD133 gene promoter [\[59](#page-11-15)]. In another study, overexpression of Oct4 and CD133 was observed in gefitinib-resistant NSCLC cells, PC9. Moreover, these resistant cells had CSC properties. Interestingly, it has been shown that Oct4 is one of the most important factors for maintaining resistance to gefitinib in lung CSCs, which can be further enhanced by hypoxia [[60\]](#page-11-16).

Stem-like cancerous cells in prostate cancer have also stemness features including differentiation, self-renewal, and tumor recurrence. Prostate CSCs express the stemness factors including Nanog, and to a lesser extent, Oct4, CD133, and NESTIN. Similarly, HIF-1α is highly expressed by prostate cancer cells and plays an important role in tumorigenesis. Moreover, hypoxia enhances the formation of prostaspheres in prostate cancer cells, which was associated with the upregulation of CSC markers including Nanog, EZH2, Oct4, EpCAM, and CD44. It has been shown that the expression of Nanog highly correlates with HIF-1 α levels in prostate cancer cells, implying their cooperative action in prostate carcinogenesis [\[61](#page-11-17)]. Similarly, the culture of PC3 and DU145 cells under hypoxia led to overexpression of HIF-1α and HIF-2α, which was associated with the upregulation of CSC factors including CD44, Nanog, Oct3/4, and ABCG2 and stemness features [[62\]](#page-11-18). Exposure of LNCaP, PC-3, and DU145 prostate cancer cells to hypoxia also led to the upregulation of another CSC marker, Sox2, which is involved in the invasion of cancer cells and sphere formation. Accordingly, the silencing of HIF-1 α resulted in the downregulation of Sox2 and suppressed the invasion of tumor cells [\[63](#page-11-19)]. Kuphal and colleagues have demonstrated that hypoxia and HIF-1 α enhance the overexpression of LIF in melanoma cells. Moreover, the expression of LIF was associated with the upregulation of CSC markers such as Nanog, Sox2, GBX2, and Oct3/4 [[64\]](#page-11-20). Nanog promotes the tumorigenic potential of B16–F10 melanoma cells under hypoxic conditions, which is associated with the acquisition of CSC-like properties. Silencing Nanog in B16–F10 cells in combination with the melanocyte differentiation antigen, tyrosinaserelated protein-2 peptide-based vaccination, TRP-2180–188, resulted in tumor regression [[65\]](#page-11-21)

4.2. CD44 and ALDH

CD44 and aldehyde dehydrogenase are two critical factors of CSCs. It has been shown that hypoxia can also promote the induction and development of CSCs through these two factors in various cancers.

Breast cancer stem cells (BCSCs) constitute a small group of cells in breast cancer with the ability to undergo self-renewal and induce chemo-resistant and secondary tumors. They show cellular heterogeneity for maintenance of tumorigenesis ability following several rounds of division. BCSCs are usually identified by aldehyde dehy-drogenase 1(ALDH)^{high} CD44⁺ CD24^{dim} expression profile [[66\]](#page-11-46). CD44 is a cell surface-expressed glycoprotein with alternatively spliced variants, which acts as a cell adhesion molecule and is overexpressed in CSCs and associated with metastasis and cancer progression [\[67](#page-11-47)]. Induction of hypoxia in MDA-MB-231 and SUM-149 breast cancer cells using CoCl2 was associated with the upregulation of CD44 implying the role of hypoxia in the induction of CSC associated molecules ([Fig. 1](#page-5-0)). Hypoxia also regulates the expression of CD44v8 and CD44v6 isoforms of CD44 in MDA-MB-231 breast cancer cells. These reports indicate the role of the hypoxic tumor microenvironment, particularly HIF-1 α , in the upregulation of CD44 and cancer progression [[68](#page-11-22)]. Liang and coworkers demonstrated that the culture of ovarian cancer cell lines OVCAR-3 and ES-2 cells under hypoxic conditions enhances the expression of HIF-1α and HIF-2α, which are associated with enrichment of CD44 bright cells with stemness characteristics [[69\]](#page-11-23).

High activity of ALDH is also associated with stem cell features including self-renewal, metastasis, tumorigenesis and poor prognosis in breast cancer. ALDH enzymes are involved in various processes such as oxidative metabolism, cell differentiation, and drug resistance. Therefore, BCSCs can be identified by ALDH expression [\[70](#page-11-48)]. Interestingly, HIF-1 α can induce the expression of ALDH1A1 in breast cancer cells under hypoxic conditions. HIF-1 α induced expression of Jagged-1, TGF-β, and Notch-1 in ALDH-expressing BCSCs, which was associated with EMT-related factors, such as Snail, Slug, and E-cadherin. On the other hand, silencing HIF-1 α in BCSCs leads to the downregulation of Oct4 and Nanog [\[71](#page-11-24)]. Kim and colleagues also demonstrated that ALDH expression was associated with HIF-2α expression in breast cancer cell lines and samples. Moreover, exposure of breast cancer cells to the diethylaminobenz aldehyde (DEAB), ALDH inhibitor, suppressed HIF-2α expression and self-renewal in BCSCs derived from 4T1 cells [[72\]](#page-11-25). It has also been reported that HIF can enhance the induction of CSCs by epigenetic-dependent mechanisms. HIF-mediated upregulation of ALKBH5 in MCF-7 and MDA-MB-231 cells negatively impacted m6A modification of Nanog mRNA, leading to increased Nanog mRNA demethylation, stabilization, expression and thereby upregulation of ALDH in BCSCs. Consequently, silencing ALKBH5 led to reduced HIFmediated sphere formation and thereby reduced the frequency of BCSCs

Fig. 2. Chemotherapy-dependent induction of stem cell factors. Chemotherapeutics such as Carboplatin, Gemcitabine, and Paclitaxel can enhance the expression of stem cell factors in tumor cells via inducing HIF-1α expression in the tumor microenvironment. Expression of GSTO1 in a HIFdependent manner increases intracellular Ca^{2+} and activates PYK2/SRC/STAT3 signaling, resulting in the expression of IL-6 and stem cell factor. IL-6 can phosphorylate STAT3 in JAK-mediated manner and enhance the expression of stem cell factors in a positive feedback loop. HIF-dependent activation of SLC7A11 and GCLM increases the synthesis of glutathione, which led to the expression of pluripotency factors and the induction of breast cancer stem cells. There are different types of agents, which inhibit expression of HIF-1α and hypoxia-induced stem cell factors, including Digoxin, Acriflavine, Curcuminderived synthetic analog (CDF) and TX-402.

under hypoxic conditions [[73\]](#page-11-26).

4.3. Adenosine/STAT3/IL-6 pathway

Adenosine, STAT3, and IL-6 are other hypoxia-related factors in the tumor microenvironment that can drive the induction of CSCs. Hypoxia can promote the induction and expansion of BCSCs via adenosine metabolism. Adenosine is one of the important immunosuppressive factors in the tumor microenvironment that promotes tumorigenesis via var-ious mechanisms [[74\]](#page-11-49). It is well-known that HIF-1 α increases the expression of adenosine-generating enzymes including CD73 and CD39 [75–[77\]](#page-11-50) in association with adenosine receptors such as A2AR and A2BR [[78,](#page-11-51)[79](#page-11-52)]. Accordingly, silencing HIF-1 α in MCF-7 cells using shRNA led to the downregulation of A2BR in these cells under hypoxic conditions. It has also been demonstrated that HIF-1α enhances the development of BCSCs through phosphorylation and activation of PKCδ in the adenosine/A2BR-dependent manner [\(Fig. 1\)](#page-5-0). PKCδ activates STAT3 and its nuclear translocation, which leads to the upregulation of Nanog and IL-6, which are critical factors for the development and maintenance of BCSCs. Moreover, blockade of IL-6 in adenosine-stimulated MDA-MB-231 and MCF-7 cells by neutralizing antibodies can potently decrease BCSCs. Similarly, silencing A2BR in MDA-MB-231, MCF-7, and SUM149 cells, robustly decreased BCSCs. Therefore, signaling of A2BR can promote the development of BCSCs in part through the upregulation of IL-6 and Nanog [[80\]](#page-11-27). Moreover, HIF-1/IL-6 and C/ EBPδ exhibit a positive feedback loop in which HIF-1 and IL-6 increase expression of C/EBPδ which in turn it amplifies both IL-6 and HIF-1. This positive regulation is relevant due to the ability of C/EBPδ to promote the development and phenotype of CSCs. Accordingly, blockade of C/EBPδ has been associated with the downregulation of stem cell factors and stemness markers [[81,](#page-11-53)[82\]](#page-11-54). Interestingly, hypoxia also promotes cancer stemness in the MDA-MB-231 triple-negative breast cancer cell line partly through STAT3. Therefore, targeting STAT3 can also be considered as a potent therapeutic approach [[17,](#page-10-16)[18](#page-10-17)]. HIF-1 α can induce STAT3 via the JAK pathway, which promotes the self-renewal of GSCs under hypoxic conditions. The secretion of VEGF in response to hypoxia is critical for stimulation of STAT3 and subsequent self-renewal of GSCs; inhibition of VEGF secretion by Brefeldin A and EHT-1864 agents potently suppress GSC self-renewal and tumor growth [[83\]](#page-11-28).

Exposure of H157 and A549 NSCLC cells to accumulating concentrations of cisplatin led to the development of resistant cell lines with CSC characteristics such as expression of CD133, Nanog, Oct4, and

ALDH [[84\]](#page-11-29). Moreover, the treatment of tumor-bearing mice by cisplatin resulted in enrichment of CD133⁺CXCR4⁺ and CD133⁺ABCG2⁺ cells with drug-resistant, metastatic and high mobility properties [[57\]](#page-11-45). The appearance of these characteristics was partly associated with IL-6-dependent upregulation of HIFs in cancer cells. Interestingly, blockade of IL-6 or HIF could potently arrest the expression of CSC markers in these cells [[84\]](#page-11-29). Consequently, targeting IL-6 or HIFs can suppress the development of CSCs and cancer recurrence in patients with lung cancer. Hasmim and colleagues demonstrated that Nanog facilitates hypoxiamediated resistance of lung carcinoma cells to CTL-induced lysis. Nanog was overexpressed in cancer cells under hypoxic conditions. Accordingly, silencing Nanog promoted CTL-dependent killing of lung carcinoma cells and cancer cell growth arrest under hypoxic conditions. Also, the downregulation of Nanog was associated with blockade of STAT3 activation. These observations show that hypoxia-mediated Nanog expression by lung carcinoma cells enhances resistance to CTLmediated killing [[85\]](#page-11-30).

4.4. MAPK/ERK pathway

MAPK/ERK signaling pathway is one of the most important mechanisms used by hypoxia to induce CSCs. HIF-1 α in the hypoxic tumor microenvironment enhances the development of BCSCs and thereby cancer progression and recurrence. Downregulation of stem cell factor (SCF), in response to HIF-1 α silencing in MCF-7 cells, has been demonstrated. HIF-1 α binds to an HRE region in the SCF promoter as shown by chromatin immunoprecipitation (CHIP assay). It has also been demonstrated that SCF is a critical factor in cancer growth and angiogenesis. Moreover, it has also demonstrated that EGF increases SCF expression in MCF-7 cells under normoxia in a HIF-1α-dependent manner [[86\]](#page-11-31). Another study showed that IL-1β also enhanced the expression of SCF in MCF-7 cells via induction of HIF-1 α in a PI3K/ mTOR pathway-dependent manner. Consequently, silencing HIF-1 α in these cells reduced the expression of SCF following stimulation with IL-1β [[87\]](#page-12-0). HIF can also propagate BCSCs in response to chemotherapy in part through induction of glutathione via activating cystine transporter xCT and the glutamate-cysteine ligase. Blockade of xCT or glutamatecysteine ligase reflects the importance of glutathione in the development of BCSCs ([Fig. 2\)](#page-7-0). Glutathione enhances FoxO3 nuclear translocation, which in turn stimulates the expression of Nanog in BCSCs. The blockade of a MEK1-ERK signaling pathway is another mechanism by which glutathione activates FoxO3. Moreover, inhibiting either FoxO3, xCT, glutamate-cysteine ligase, or Nanog can prevent chemotherapymediated induction of BCSCs and tumor recurrence [[88\]](#page-12-1). Culture of MCF-7, MDA-MB-231, SUM-149, and HCC1954 cells under hypoxic conditions led to the upregulation of glutathione S-transferase omega1 (GSTO1), which was associated with increased frequency of ALDH⁺ BCSCs and upregulation of Nanog, Sox2, and KLF4 in MCF-7 and MDA-MB-231 cells. It is demonstrated that GSTO1 increases cytosolic Ca^{2+} levels, which leads to the induction of the PYK2/SRC/STAT3 signaling pathway, resulting in the upregulation of BCSCs [\[89](#page-12-2)]. HIF also enhances the enrichment of BCSCs via activation of the mitogen-activated protein kinase (MAPK) pathway. Treatment of SUM-149 and MDA-MB231 breast cancer cells with chemotherapeutics induced DUSP9 and reduced DUSP16 by HIF resulting in blockade of ERK and stimulation of p38, which led to upregulation of Nanog and KLF4 and enrichment of BCSCs. Inhibition of ERK blocks nuclear localization of FoxO3 and induces expression of Nanog. Stimulation of p38 stabilizes the mRNA of Nanog and KLF4 via the inactivation of ZFP36L1 [\[90](#page-12-3)].

HIF-1 can expand GSCs in association with growth factor signaling pathways. This has been demonstrated by blockade of ERK1/2 or PI3K-Akt pathways, which suppressed the hypoxia-induced expansion of CD133-expressing GSCs [[91\]](#page-12-4). HIF-2 can upregulate prostatic acid phosphatase (PAP) in hypoxic GSCs. PAP subsequently facilitates adenosine production, which in turn binds to A2BR and enhances the expansion of GSCs and tumorigenesis through activation of Akt and Erk-1/2 pathways [[92\]](#page-12-5).

Cancer-associated fibroblasts (CAFs) are an important non-cancer group of cells in the tumor microenvironment. Interestingly, it is demonstrated that CAFs enhance development and EMT of prostate CSCs partly by stimulating the HIF-1α/β-catenin signaling pathway. Accordingly, blockade of HIF-1α/β-catenin signaling in LNCaP cells resulted in the downregulation of mesenchymal markers including Ncadherin, Fibronectin, and Vimentin [[93\]](#page-12-6). Another pathway by which CAFs promote EMT in PC3 cells is by activating the monoamine oxidase A (MAOA)/mTOR/HIF-1α signaling pathway. CAFs can also increase oxidative stress through the same pathway, which promotes cancer progression. Moreover, they upregulate IL-6 receptor and CXCR4 in prostate cancer cells [\[94](#page-12-7)]. This is important because it has been shown that prostate CSCs secrete high amounts of IL-6, which enhances selfrenewal [\[95](#page-12-8)]. Interestingly, the treatment of PC3 cells with curcumin could potently suppress EMT by enhancing E-cadherin and reducing vimentin expression. Furthermore, it prevents oxidative stress and expression of IL-6 receptor and CXCR4 by suppressing the MAOA/mTOR/ HIF1 α pathway [\[94](#page-12-7)]. It has been suggested that targeting MAOA may serve as a potent anti-CSC therapeutic strategy in prostate cancer. MAOA enhances HIF-1α/VEGF-A/AKT signaling pathways, reduces PTEN expression, increases expression of stemness markers, and promotes the development of CSCs via HIF-1 α pathways in prostate cancer. Consequently, silencing MAOA in LNCaP cells can potently suppress the formation of spheroids [\[96](#page-12-9)].

4.5. NOTCH and WNT signaling

Hypoxia exploits NOTCH and WNT signaling pathways to regulate the development of CSCs. It has been suggested that the Notch pathway is required for HIF-1 α -induced maintenance of GSCs. Accordingly, Qiang and colleagues showed that exposure of U251-derived stem-like tumor sphere cells to hypoxia-induced upregulation of HIF-1 α and NICD. HIF-1α stabilizes NICD and upregulates the Notch Delta ligand (DLL1) thereby increasing expression of Notch downstream factors, such as Hes1 and Hey2. STAT3 is also involved in the maintenance of GSCs by upregulation of HIF-1 α and promoting hypoxia-mediated sti-mulation of the Notch signaling pathway [[97\]](#page-12-10). Although both HIF-1 α and HIF-2 α bind to NICD, HIF-1 α is more stabilized in hypoxic conditions and its binding to NICD enhances expression of Notch responsive genes. On the other hand, under mild hypoxia or normoxia, HIF-2α enhances stem cell-related factors such as Oct4 and prevents the expression of Notch target genes [\[98](#page-12-11)]. Wang and coworkers demonstrated

that HIF-1α enhances the Notch-mediated induction of Hes1, which is an important factor for LSCs stemness, self-renewal and cancer recurrence. Hes1 has an autoregulation mechanism, which is counteracted blocking binding to the N-box of its promoter by HIF-1 α [[99\]](#page-12-12). It has also been demonstrated that a small population of Wnt-active cells seen in T-ALL possess stem-like self-renewal properties, robustly induced by HIF-1α-mediated transcription of β-catenin under hypoxic conditions [[100](#page-12-13)]. Seo and coworkers demonstrated that the hypoxia/NOTCH1/ Sox2 axis are crucial factors for the development of ovarian CSCs, and can thereby serve as candidates for novel anti-CSC therapeutics for ovarian cancer. They showed that hypoxia in association with Notch signaling promotes drug resistance and self-renewal of ovarian CSCs. Indeed, Notch signaling facilitates hypoxia-induced upregulation of Sox2, which promotes drug resistance in ovarian cancer cells through the upregulation of ABCB1 and ABCG2. Sox2 can also promote sphere formation and induce CSCs characteristics. Consequently, silencing Sox2 abolishes hypoxia-mediated induction of CSC characteristics [[101](#page-12-14)]. The culture of MCF-7 cells under hypoxic conditions gradually increased the expression of HIF-2α, which was associated with resistance to PTX chemotherapy and expression of stem cell markers including Nanog, c-Myc, and Oct4. HIF-2 α induces Notch and Wnt signaling pathways in MCF7 and MDA-MB231 cells, which enhance the expression of c-Myc and induce phenotype of CSC [\[102\]](#page-12-15).

4.6. Other mechanisms

In addition to the above-mentioned mechanisms, there are several mechanisms by which HIFs enhance the development of CSCs. The influence of hypoxia on BCSCs can be mediated by TAZ protein. It has been shown that the expression and function of TAZ protein, encoded by the WWTR1 gene, is significantly increased in BCSCs from patients with advanced disease [\[103\]](#page-12-25). Exposure of various breast cancer cell lines including MCF10A, HCC-1954, MCF-7, MDA-MB-435, and MDA-MB-231 to both hypoxic and normoxic conditions showed that upregulation of TAZ protein is due to binding of HIF-1 α to the HRE in the promoter of the WWTR1 gene. Furthermore, HIF-1 α enhances nuclear localization of TAZ by increasing the ubiquitination and degradation of LATS2 kinase, an inhibitor of TAZ nuclear localization, via binding to HRE in the ubiquitin protein ligase SIAH1 gene. Consequently, silencing SIAH1, TAZ, or HIF-1α by shRNA potently decreased BCSCs under hypoxic conditions [\[104\]](#page-12-16). Another way by which HIF signaling promotes stemness of breast cancer cells is through induction of integrin alpha 6 (ITGA6, which is also known as CD49f). Accordingly, it has been shown that the upregulation of ITGA6 by HIF signaling modulates stem cell-like features and invasion of cancer cells in metastatic breast cancer cells such as MDA-MB-231 and polyoma middle T (MMTV-PyMT) cells [\[105\]](#page-12-17).

The regulation of the PAX3/P53 axis is an important mechanism, which controls the development of GSCs by HIF-1 α . HIF-1 α upregulates PAX3, which is pivotally involved in regulating carcinogenesis, migration, and self-renewal of GSCs by binding to the promoter region of p53 and suppressing its expression [[106](#page-12-18)]. Monocarboxylate transporter 4 (MCT4) is another factor induced under hypoxic conditions by HIF. Overexpression of MCT4 in GBM patients is associated with the expansion and survival of GBM stem-like cells. The knockdown of MCT4 by shRNA also reduces the frequency of $CD133⁺$ cells and suppresses HIF transcriptional function [[107](#page-12-19)]. GSCs express high levels of Mixed-Lineage Leukemia1 (MLL1), an epigenetic-modifying protein, which is a critical factor for growth, self-renewal, and tumorigenicity of GSCs. It has been shown that MLL1 upregulates HIF-2 α and its downstream genes, such as VEGF, in glioma cells [[108](#page-12-20)]. GSCs also overexpress CDH5 (also known as vascular-endothelial–cadherin or CD144) under hypoxic conditions, which enhance TGF-β-dependent tumor progression. It has also been demonstrated that HIF-1 α and HIF-2 α upregulate CDH5 in GSCs under hypoxic conditions [\[109\]](#page-12-21).

Leukemia stem cells (LSCs) exhibit high self-renewal capacity, large

expansion, preferred homing to the bone marrow niche in association with robust tumorigenic features. Although several factors in tumor microenvironment help maintain multipotency and self-renewal of hematopoietic stem cells (HSCs) within the niche, hypoxia, and HIFs are also essential for this process [[110\]](#page-12-26). It has been demonstrated that BCR-ABL-expressing HSCs (Lin⁻Sca-1⁺c-Kit⁺ cells) in mouse AML overexpress HIF-1α and its downstream genes including VEGF, TGF-α, and GLUT1 and act as LSCs. HIF-1 α was also a critical factor for development of CML and maintenance of LSCs, as demonstrated in HIF-1α-deficient mice used in a bone marrow transplantation (BMT) model. The lack of HIF-1 α led to the induction of apoptosis and cell cycle arrest through upregulation of tumor suppressor genes such as p53, p 16^{Ink4a} . and $p19^{Arf}$ in LSCs [[111](#page-12-22)].

It has been reported that SIRT1, a member of the sirtuin family, has been detected in some cancers such as colon cancer, prostate cancer, breast cancer, and is associated with carcinogenesis, cell proliferation, EMT phenotype, and differentiation [[112](#page-12-27),[113\]](#page-12-23). SIRT1 is also related to poor prognosis and chemoresistance in ovarian cancer [\[114\]](#page-12-28). SIRT1 is the downstream target gene of HIF-1 α and can be induced by hypoxic conditions that are associated with the promotion of CSC properties in ovarian cancer cells. The NF-κB signaling pathway, which is activated by hypoxia, is involved in hypoxia-induced SIRT1 upregulation. Therefore, targeting SIRT1and HIF-1 α are potential therapeutic strategies for the treatment of ovarian cancer [\[115\]](#page-12-24).

5. Targeting HIFs as a therapeutic approach

Recent studies have shown that HIF-1 can mediate resistance to radiation and chemotherapy, therefore, inhibition of HIF-1 activity can provide a novel therapeutic opportunity for cancer. One of the molecules intervening HIF-1 expression is EZN-2698 (an RNA antagonist) which can bind specifically and hinder the expression of HIF-1α mRNA and target genes. Tumor progression and expression of HIF-1 α protein is inhibited by EZN-2698 [[116](#page-12-29)]. Hypoxia can promote tumor progression and induce CSCs by regulating miRNAs. Hypoxia upregulates miR-21 in prostate cancer cells, which correlates with increased self-renewal of prostate CSCs [[95\]](#page-12-8). Accordingly, exposure of prostate cancer cells to curcumin-derived synthetic analog (CDF) suppressed hypoxia-mediated migration of prostate cancer cells and inhibited the formation of prostaspheres partly by downregulating HIF-1 α , miR-210, miR-21, and CSC markers [[95\]](#page-12-8). Similarly, treatment of PC-3 cells with another anticancer agent, Pristimerin, leads to suppression of hypoxia-mediated expansion and EMT and prevents sphere formation, colony formation and expression of CSC markers including CD44, Oct4, AGO2, and KLF4 [[117](#page-12-30)]. Therefore, curcumin and Pristimerin are potential anti-cancer treatments for inhibition of hypoxia-mediated induction of prostate CSCs. Overall, prostate cancer cells express both HIF-1α and HIF-2α under hypoxic conditions and acquire stem-like properties and upregulate stem cell factors. Treatment with curcumin-derived synthetic analog (CDF) and Pristimerin may be a potential strategy for the suppression of hypoxia-induced CSC properties and the prevention of prostate cancer progression. Cardiac glycoside (Digoxin) is a cognitive drug for the treatment of congestive heart failure. Surprisingly, it has been shown that this drug can inhibit the expression of HIF-1 α protein and HIF-2 α mRNA expression [\[118\]](#page-12-31). Inhibition of HIF-1 α by Digoxin, promoted suppression of downstream targets such as VEGF, Glut1, and CA9, which are associated with GSC properties such as self-renewal, angiogenesis, invasiveness and downregulation of CD133 [[119](#page-12-32)]. It is proposed that inhibition of HIF-1α can be considered as a potent anti-LSC therapeutic strategy in CML. Consequently, the treatment of CML cells with the HIF-1 inhibitor, Acriflavine (ACF), potently suppressed the stemness capacity of CML cells and inhibited maintenance of LSC and growth of CML cells. ACF potently inhibited the expression of important stemness-promoting molecules including Nanog, Oct4, c-MYC, and Sox2 [\[120\]](#page-12-33). Downregulation of HIF-1 α and HIF-2 α expressed by CaOV3 and SKOV3.ip1 ovarian cancerous cells by TX-402 treatment,

an analog of tirapazamine, leads to reduced expression of CSC markers including CD44 and CD133 and stem cell characteristics [[121](#page-12-34)]. It has also been reported that interaction of Nanog with signaling axis of androgen receptor drives the development of ovarian CSCs [[122](#page-12-35)] Cotreatment by ursolic acid and cisplatin can considerably reduce the resistance of ovarian CSCs to cisplatin. Under hypoxic conditions, ursolic acid can suppress the proliferation of ovarian CSCs and promote their sensitivity to chemotherapeutic drugs by downregulation of HIF-1α and ABCG2. The PI3K/Akt signaling pathway, which is activated by hypoxia, has a critical role in ursolic acid-dependent suppression of HIF-1 α and ABCG2 expression [\[123](#page-12-36)]

6. Conclusion

Previous studies have demonstrated a profound connection between the hypoxic tumor microenvironment, HIFs, and CSC specification and maintenance [\[10](#page-10-9)[,124\]](#page-12-37). CSCs have been detected in several cancers such as AML, colon, lung, breast, brain, liver, pancreas, ovarian, prostate, and melanoma [[125](#page-12-38)[,126\]](#page-12-39), and characterized by expression of different cell surface glycoproteins depending on the tissue origin. Beside selfrenewal, CSCs, can give rise to differentiated tumor cells and play a crucial role in tumor formation [[127](#page-12-40)]. The eradication of CSCs can potentially facilitate remission, as they are the main causes of cancer recurrence and metastasis. Therefore, targeting CSCs based on their cell surface markers is a good therapeutic strategy. For instance, therapeutic-targeting of CD133 holds promise for the eradication of CSCs due to its expression by CSCs in various solid tumors, [[128](#page-12-41)]. Furthermore, the use of nanomaterials has also been explored as a strategy for the targeted destruction of CSCs [\[129\]](#page-12-42). The use of CD133-specific peptide-coated gold nanoparticles as imaging agents facilitated the diagnosis of GBM and served as a drug carrier for therapeutic approaches [[130](#page-12-43)]. However, the cellular heterogeneity, development, and interaction of CSCs with the tumor microenvironment, making it difficult to specifically target these cells in cancer patients [[131](#page-12-44)]. Immunotherapeutic strategies should selectively target both CSCs and differentiated tumor cells, as CSCs can give rise to differentiated tumor cells and play a crucial role in tumor formation. On the other hand, differentiated cancer cells enhance the generation of CSCs. Therefore, immunotherapy strategies that target both CSCs and differentiated tumor cells will be more beneficial and achieve better clinical impact [[127](#page-12-40)].

In addition to the identification of CSC specific markers for selective targeting of these cells, other questions in the relation between hypoxia and CSC; which one is more important for induction and development of CSCs, HIF1 or HIF-2? Various studies have been demonstrated that HIF-2 α enhances expression of target genes required for the enrichment of CSCs under normoxic conditions [\[132\]](#page-12-45), however, HIF-1 has a stronger potential for inducing CSCs under hypoxic conditions compared to HIF-2. In our opinion, the tumor microenvironment efficiently preserves the properties of CSCs and provides conditions, which are essential for the development of CSCs during tumor initiation, development, and regression (following chemotherapy) by providing HIF factors. Both HIF-1 α and HIF-2 α are required for the development of CSCs, as they manage different stages of development. HIF-1 α is the main HIF factor during tumor growth, which is associated with the generation of the hypoxic area in the tumor center, whereas HIF-2 α is active following treatment such as chemotherapy and radiation that significantly decrease tumor size and provide normoxic conditions. Although based on current knowledge this model seems to be rational, it needs to be approved by performing further precise studies.

Based on the both in vitro and in vivo results derived from preclinical studies, targeting HIFs can suppress metastasis-initiating cells and thereby inhibit tumor recurrence [[119](#page-12-32)]. Blockade of HIFs in association with their signaling mediators and combined with immune checkpoint inhibitors may be effective for eradicating total tumor mass without the risk of CSC-induced cancer recurrence. HIF-1α can regulate PD-L1 expression by directly interacting with the PD-L1 proximal promoter. Also, PD-L1 and HIF-1α co-expression in hypoxic conditions abrogate T cell function. Consequently, the inhibition of PD-L1 signaling in hypoxic conditions increases the sensitivity of cancer cells to T cell-mediated killing and abolishes the function of tumor-associated immune cells [[133](#page-12-46)[,134\]](#page-12-47). Therefore, combining HIF-1 α blockade with negative immune checkpoint inhibitor treatment may be a more effective therapeutic strategy.

Understanding the differences between tumor-initiating and chemo/radiotherapy-induced CSCs for stemness, specificity, stability and sustained expression of CSC markers properties is relevant for future therapeutic studies. Moreover, the effect of HIF factors on different stages of CSC development is also of importance.

The development of new potent and selective HIF inhibitors is required to supplement others such as Digoxin and Pristimerin. Assessing the clinical benefits will facilitate the design and development of a new generation of drugs, which can robustly target and block the expression of HIF factors. Additionally, novel nano-based drug delivery systems can be used to increase the detection of intracellularly-expressed HIF factors at tumor sites [\[135\]](#page-12-48). The use of HIF-1 α -specific siRNA-loaded nanoparticles can efficiently decrease the expression of HIF-1 α and inhibit tumor metastasis [[136](#page-12-49)]. Drug delivery systems are one of the most efficient agents to be used for targeted therapy-they can simultaneously target various pathways, decrease the side effect of traditional treatments, increase the concentration of drug in the tumor niche thereby preventing the resistance of cancer cells to current chemotherapy drugs [[129](#page-12-42),[137](#page-12-50)[,138\]](#page-12-51).
